Train, Validate, Test

Recap of Basic Neural Networks (and some Deep Network Fundamentals)

Jonathon Hare and Antonia Marcu

Vision, Learning and Control University of Southampton

Classical Types of Learning

- Supervised Learning learn to predict an output when given an input vector
- Unsupervised Learning discover a good internal representation of the input
- Reinforcement Learning learn to select an action to maximize the expectation of future rewards (payoff)
- Semi-supervised Learning learn with few labelled examples and many unlabelled ones

Jonathon Hare and Antonia Marcu

COMP6258

3 / 25

Other Types of Learning

- Self-supervised Learning learn with targets induced by a prior on the unlabelled training data
- Active Learning learn by seeking guidance from human or oracle when needed (iterative semi-supervised learning)
- Continual Learning learn new tasks/classes sequentially (iterative supervised/unsupervised learning)
- Online learning learning one example at a time sequentially (iterative supervised learning)

Jonathon Hare and Antonia Marcu

Two Types of Supervised Learning

- Regression: The machine is asked predict k numerical values given some input. The machine is a function $f: \mathbb{R}^n \to \mathbb{R}^k$.
- Classification: The machine is asked to specify which of *k* categories some input belongs to.
 - Multiclass classification target is one of the k classes
 - Multilabel classification target is some number of the k classes
 - In both cases, the machine is a function $f: \mathbb{R}^n \to \{1, ..., k\}$.
- It is most common for both types of algorithms to actually learn $\hat{f}: \mathbb{R}^n \to \mathbb{R}^k$.

COMP6258

5 / 25

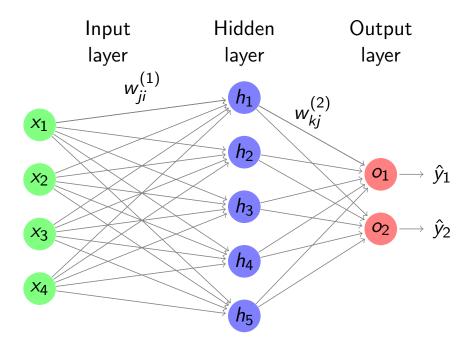

How Supervised Learning Typically Works

- Start by choosing a model-class: $\hat{y} = f(x; W)$ where the model-class f is a way of using some numerical parameters, W, to map each input vector x to a predicted output \hat{y} .
- Learning means adjusting the parameters to reduce the discrepancy between the true target output y on each training case and the output \hat{y} , predicted by the model.

Jonathon Hare and Antonia Marcu

COMP6258

Let's look at a Multilayer Perceptron (without biases)...

Without loss of generality, we can write the above as:

$$\hat{\mathbf{y}} = g(f(\mathbf{x}; \mathbf{W}^{(1)}); \mathbf{W}^{(2)}) = g(\mathbf{W}^{(2)}f(\mathbf{W}^{(1)}\mathbf{x}))$$

where f and g are activation functions.

COMP6258

7 / 25

Common Activation Functions

- Identity
- Sigmoid (aka Logistic)
- Hyperbolic Tangent (tanh)
- Rectified Linear Unit (ReLU) (aka Threshold Linear)

Final layer activations

$$\hat{\boldsymbol{y}} = g(\boldsymbol{W}^{(2)}f(\boldsymbol{W}^{(1)}\boldsymbol{x}))$$

- What form should the final layer function g take?
- It depends on the task (and on the chosen loss function)...
 - ullet regression o typically linear
 - binary classification \rightarrow typically Sigmoid
 - ullet multilabel classification o typically Sigmoid
 - ullet multiclass classification o typically Softmax

Jonathon Hare and Antonia Marcu

COMP6258

9 / 25

Softmax

$$\mathsf{softmax}(\pmb{z})_i = rac{e^{z_i}}{\sum_{j=1}^K e^{z_j}} \qquad \forall i=1,2,\ldots,K$$

- Note that softmax makes reference to all the elements in the output.
- output: positive numbers that sum to 1.
- Note:

$$\frac{\partial \operatorname{softmax}(\mathbf{z})_{i}}{\partial z_{i}} = \operatorname{softmax}(z_{i})(1 - \operatorname{softmax}(z_{i}))$$

$$\frac{\partial \operatorname{softmax}(\mathbf{z})_{i}}{\partial z_{j}} = \operatorname{softmax}(z_{i})(1(i = j) - \operatorname{softmax}(z_{j}))$$

$$= \operatorname{softmax}(z_{i})(\delta_{ij} - \operatorname{softmax}(z_{j}))$$

Ok, so let's talk loss functions

- The choice of loss function depends on:
 - the task (e.g. classification/regression/something else)
 - the activation function of the last layer
 - For numerical reasons many times the activation is computed directly within the loss rather than being part of the model
- Some classification losses require raw outputs (e.g. a linear layer) of the network as their input
 - These are often called unnormalised log probabilities or logits
 - An example would be hinge-loss used to create a Support Vector Machine for binary classification.
- There are many different loss functions we might encounter (MSE, Cross-Entropy, KL-Divergence, huber, L1 (MAE), CTC, Triplet, ...) for different tasks.

The Loss Function (measure of discrepancy)

Recall from Foundations of Machine Learning:

 Mean Squared Error (MSE) loss for a single data point is given by

$$\ell_{MSE}(\hat{\boldsymbol{y}}, \boldsymbol{y}) = \sum_{i} (\hat{y}_i - y_i)^2 = (\hat{\boldsymbol{y}} - \boldsymbol{y})^{\top} (\hat{\boldsymbol{y}} - \boldsymbol{y})$$

- We often multiply this by a constant factor of $\frac{1}{2}$ can anyone guess/remember why?
- $\ell_{MSE}(\hat{y}, y)$ is the predominant choice for regression problems with linear activation in the last layer
- For a classification problem with Softmax or Sigmoidal activations MSE can cause slow learning
 - Gradients of ℓ_{MSE} are proportional to the difference in target and predicted value, multiplied by the gradient of the activation function
 - The Cross-Entropy loss function is generally a better choice in this case

Binary Cross-Entropy

For the binary classification case:

$$\ell_{BCE}(\hat{y}, y) = -y \log(\hat{y}) - (1 - y) \log(1 - \hat{y})$$

- The cross-entropy loss function is non-negative, $\ell_{BCE}>0$
- $\ell_{BCE} \approx 0$ when the prediction and targets are equal (i.e. y=0 and $\hat{y}=0$ or when y=1 and $\hat{y}=1$)
- With Sigmoidal final layer, $\frac{\partial \ell_{BCE}}{\partial \boldsymbol{W}_{i}^{(2)}}$ is proportional to just the error in the output $(\hat{y} y)$ and therefore, the larger the error, the faster the network will learn!
- Note that the BCE is the negative log likelihood of the Bernoulli Distribution

Binary Cross-Entropy — Intuition

- The cross-entropy can be thought of as a measure of surprise.
- Given some input x_i , we can think of \hat{y}_i as the estimated probability that x_i belongs to class 1, and $1 \hat{y}_i$ is the estimated probability that it belongs to class 0.
- Note the extreme case of infinite cross-entropy, if your model believes that a class has 0 probability of occurrence, and yet the class appears in the data, the 'surprise' of your model will be infinitely great.

Binary Cross-Entropy for multiple labels

In the case of multi-label classification with a network with multiple sigmoidal outputs you just sum the BCE over the outputs:

$$\ell_{BCE} = -\sum_{k=1}^{K} [y_k \log(\hat{y}_k) + (1 - y_k) \log(1 - \hat{y}_k)]$$

where K is the number of classes of the classification problem, $\hat{y} \in \mathbb{R}^K$.

Numerical Stability: The Log-Sum-Exp trick

$$\ell_{BCE}(\hat{y}, y) = -y \log(\hat{y}) - (1 - y) \log(1 - \hat{y})$$

- Consider what might happen early in training when the model might confidently predict a positive example as negative
 - $\hat{y} = \sigma(z) \approx 0 \implies z << 0$
 - if \hat{y} is small enough, it will become 0 due to limited precision of floating-point representations
 - but then $log(\hat{y}) = -inf$, and everything will break!
- To tackle this problem implementations usually combine the sigmoid computation and BCE into a single loss function that you would apply to a network with linear outputs (e.g. BCEWithLogitsLoss).
- Internally, a trick called 'log-sum-exp' is used to shift the centre of an exponential sum so that only numerical underflow can potentially happen, rather than overflow
 - Ultimately this means you'll always get a numerically reasonable result (and will avoid NaNs and Infs originating from this point).

.

Multiclass classification with Softmax Outputs

- Softmax can be thought of making the *K* outputs of the network mimic a probability distribution.
- The target label y could also be represented as a distribution with a single 1 and zeros everywhere else.
 - e.g. they are "one-hot encoded".
- In such a case, the obvious loss function is the negative log likelihood of the Categorical distribution (aka Multinoulli, Generalised Bernoulli, Multinomial with one sample)
 - Note that in practice as y_k is zero for all but one class you don't actually do this summation, and if y is an integer class index you can write $\ell_{NLL} = -\log \hat{y}_v$.

Log-Sum-Exp can be used for better numerical stability. PyTorch combines LogSoftmax with NLL in one loss and calls this "Categorical Cross-Entropy" (so you would use this with a **linear output layer**)

Reminder: Gradient Descent

- Define total loss as $\mathcal{L} = \sum_{(\mathbf{x}, y) \in \mathbf{D}} \ell(g(\mathbf{x}, \theta), y)$ for some loss function ℓ , dataset \mathbf{D} and model g with learnable parameters θ .
- Define how many passes over the data to make (each one known as an Epoch)
- Define a learning rate λ

Gradient Descent updates the parameters θ by moving them in the direction of the negative gradient with respect to the **total loss** \mathcal{L} by the learning rate λ multiplied by the gradient:

for each Epoch:
$$oldsymbol{ heta} \leftarrow oldsymbol{ heta} - \lambda
abla_{oldsymbol{ heta}} \mathcal{L}$$

Jonathon Hare and Antonia Marcu

COMP6258

Reminder: Stochastic Gradient Descent

- Define loss function ℓ , dataset ${\bf \it D}$ and model ${\it g}$ with learnable parameters ${\bf \it \theta}$.
- Define how many passes over the data to make (each one known as an Epoch)
- ullet Define a learning rate λ

Stochastic Gradient Descent updates the parameters θ by moving them in the direction of the negative gradient with respect to the loss of a **single** item ℓ by the learning rate λ multiplied by the gradient:

```
for each Epoch:  \text{for each } (\textbf{\textit{x}}, \textbf{\textit{y}}) \in \textbf{\textit{D}} \colon \\ \boldsymbol{\theta} \leftarrow \boldsymbol{\theta} - \lambda \nabla_{\boldsymbol{\theta}} \ell
```

A Quick Introduction to Tensors

Broadly speaking a tensor is defined as a linear mapping between sets of algebraic objects¹.

A tensor T can be thought of as a generalization of scalars, vectors and matrices to a single algebraic object.

We can just think of this as a multidimensional array².

- A 0D tensor is a scalar
- A 1D tensor is a vector
- A 2D tensor is a matrix
- A 3D tensor can be thought of as a vector of identically sized matrices
- A 4D tensor can be thought of as a matrix of identically sized matrices or a sequence of 3D tensors

...

¹This statement is always entirely true

Jonathon Hare and Antonia Marcu

²This statement will upset mathematicians and physicists because its not always true for them (but it is for us!).

Operations on Tensors in PyTorch

- PyTorch lets you do all the standard matrix operations on 2D tensors
 - including important things you might not yet have seen like the **hadamard product** of two $N \times M$ matrices: $\mathbf{A} \odot \mathbf{B}$)
- You can do element-wise add/divide/subtract/multiply to ND-tensors
 - and even apply scalar functions element-wise (log, sin, exp, ...)
- you can slice, reshape, and even index a single element (generally don't do that!)
- PyTorch often lets you broadcast operations (just like in numpy)
 - if a PyTorch operation supports broadcast, then its Tensor arguments can be automatically expanded to be of equal sizes (without making copies of the data).³

Tensors, batches and vectorisation

- The reality of training a model is that we neither use gradient descent or stochastic gradient descent; we do something in-between called mini-batch SGD.
- This works on batches of data (e.g. small subsets of the training set)
- These batches are assembled into a tensor
- Broadcasting is used to apply operations/functions to all the samples in the batch tensor in parallel to compute a loss vector
- the loss vector is summed/averaged using a vectorised method (e.g. .sum())

Jonathon Hare and Antonia Marcu

³Important - read and understand this after the lab: https://pytorch.org/docs/stable/notes/broadcasting.html

Tensor implementation

It's important to understand something about how tensors are implemented in software and particularly how memory copies can be avoided...

Jonathon Hare and Antonia Marcu
